ASICs or like fabrication-preprogrammed hardware provide controlled power and recovery signals to a computing system that is made up of commercial, off-the-shelf components -- and that has its own conventional hardware and software fault-protection systems, but these are vulnerable to failure due to external and internal events, bugs, human malice and operator The computing system preferably includes processors and programming that are diverse in design and source. The hardware infrastructure uses triple modular redundancy to test itself as well as the computing system, and to remove failed elements — powering up and loading data into spares. hardware is very simplified in design and programs, so that bugs can be thoroughly rooted out. Communications between the protected system and the hardware are protected by very simple circuits with duplex redundancy.
